1. What is a Load Balancer?

A **load balancer** is a server or device that distributes incoming client requests across a pool of backend servers. Without it, a single server would receive all traffic — eventually becoming overwhelmed. The load balancer ensures no single server becomes a bottleneck, improving **availability, scalability, and fault tolerance**.

Without Load Balancer	With Load Balancer
Single server handles all traffic	Traffic distributed across N servers
One server failure = complete downtime	One server failure = others absorb load
Cannot scale horizontally	Add servers behind LB to scale out
All users experience same slowdowns	LB routes to fastest/least-busy server

2. L4 vs L7 Load Balancers

L4: fast TCP/UDP routing by IP+port · L7: smart HTTP routing by headers/URL/cookies with caching & session support

3 & 4. Static Algorithms — Round Robin, Weighted RR, IP Hash

Static algorithms distribute load based on fixed, predetermined rules. They do not monitor current server state or adapt to real-time conditions. They are simpler to implement but less adaptive.

Static Load Balancing Algorithms

Round Robin: cyclic · Weighted RR: by capacity · IP Hash: session affinity · When-to-use cards below each

Round Robin: req 1→S1, req 2→S2, req 3→S3, req 4→S1... Works perfectly when all servers are identical.

Weighted Round Robin: S1(w=4) gets 4 requests, S2(w=2) gets 2, S3(w=1) gets 1 per cycle. Proportional to capacity.

IP Hash: hash(1.2.3.4) = 2 → S2 always. Same client always hits same server. Breaks if client goes via shared proxy.

5. Dynamic Algorithms — Real-Time Routing

Dynamic algorithms monitor the current state of each server and route requests based on live metrics. They adapt in real time, making them far better for production systems with variable load patterns.

Dynamic Load Balancing Algorithms

Least Connections	Weighted Least Conn	Least Response Time																																				
Route to server with fewest active connections	Route to server with lowest: $\text{conns} \div \text{weight}$	Score = $\text{active conns} \times \text{TTFB}$ → pick lowest																																				
<table> <tr> <th>Server</th><th>Active Conns</th><th>Pick?</th></tr> <tr> <td>S1</td><td>8 conns</td><td></td></tr> <tr> <td>S2</td><td>3 conns</td><td>← route here</td></tr> <tr> <td>S3</td><td>12 conns</td><td></td></tr> </table>	Server	Active Conns	Pick?	S1	8 conns		S2	3 conns	← route here	S3	12 conns		<table> <tr> <th>Server</th><th>Conns / Weight</th><th>Ratio</th></tr> <tr> <td>S1</td><td>$8 \div 4$</td><td>= 2.0</td></tr> <tr> <td>S2</td><td>$3 \div 2$</td><td>= 1.5 ← pick</td></tr> <tr> <td>S3</td><td>$6 \div 1$</td><td>= 6.0</td></tr> </table>	Server	Conns / Weight	Ratio	S1	$8 \div 4$	= 2.0	S2	$3 \div 2$	= 1.5 ← pick	S3	$6 \div 1$	= 6.0	<table> <tr> <th>Server</th><th>Conns × TTFB</th><th>Score</th></tr> <tr> <td>S1</td><td>$5 \times 20\text{ms}$</td><td>= 100</td></tr> <tr> <td>S2</td><td>$3 \times 15\text{ms}$</td><td>= 45 ← pick</td></tr> <tr> <td>S3</td><td>$8 \times 30\text{ms}$</td><td>= 240</td></tr> </table>	Server	Conns × TTFB	Score	S1	$5 \times 20\text{ms}$	= 100	S2	$3 \times 15\text{ms}$	= 45 ← pick	S3	$8 \times 30\text{ms}$	= 240
Server	Active Conns	Pick?																																				
S1	8 conns

S2	$3 \div 2$	= 1.5 ← pick																																				
S3	$6 \div 1$	= 6.0																																				
Server	Conns × TTFB	Score																																				
S1	$5 \times 20\text{ms}$	= 100																																				
S2	$3 \times 15\text{ms}$	= 45 ← pick																																				
S3	$8 \times 30\text{ms}$	= 240																																				
✓ Adapts to actual server load ✓ Real-time adjustment ✗ Ignores traffic volume per conn	✓ Load + capacity both considered ✓ Better than plain Least Conn ✓ Production recommended	✓ Best accuracy — load + speed ✓ TTFB reflects true server state ✗ Requires continuous monitoring																																				
TTFB = Time to First Byte: time from request sent to first byte received. Measures true server responsiveness.																																						

Dynamic Algorithms — Comparison		
Least Connections Real-time connection count Simple dynamic adaptation Good for uniform request sizes High connection count servers	Weighted Least Conn Mixed server capacities Real-time + capacity aware Production default choice Handles heterogeneous clusters	Least Response Time Best accuracy required Monitoring infrastructure available High-performance APIs Variable response time workloads

Least Conn: min active connections · Weighted Least Conn: $\text{conns}/\text{weight}$ ratio · Least Response Time: $\text{conns} \times \text{TTFB}$ score

TTFB — Time to First Byte

TTFB measures the time from when a request is sent to when the first byte of the response is received. It is the best proxy for how busy a server currently is. A slow TTFB = server is processing heavy requests. Least Response Time uses TTFB to route to the genuinely fastest server right now.

Algorithm	Formula	Route to	Example
Least Connections	count active conns	Server with min conns	S1=8, S2=3, S3=12 → route to S2
Weighted Least Conn	$\text{conns} \div \text{weight}$	Server with min ratio	S1=8/4=2.0, S2=3/2=1.5, S3=6/1=6 → S2
Least Response Time	$\text{conns} \times \text{TTFB}$	Server with min score	S1=5×20=100, S2=3×15=45, S3=8×30=240 → S2

6. Algorithm Deep-Dive & Trade-offs

Round Robin

- Each request goes to next server in rotation: S1, S2, S3, S1, S2, S3...
- No state tracking — LB does not know if servers are busy or free
- Problem: if S1 is 2x slower, it receives the same count as S2 and gets overwhelmed
- Fix: Use Weighted Round Robin when server specs differ

Weighted Round Robin

- Assign weights proportional to server CPU/RAM capacity
- S1 (8 core, 32GB) → $w=4$, S2 (4 core, 16GB) → $w=2$, S3 (2 core, 8GB) → $w=1$
- Still static — if S1 gets 4 long-running requests it may still be slower than S2 with 2 quick ones
- Weights set at server registration time — do not update dynamically

IP Hash

- Client IP hashed to a bucket → always same server. Useful for stateful sessions.
- If corporate users route via NAT/proxy, ALL share one IP → all requests go to one server
- Modern apps use sticky sessions via cookie instead (more reliable than IP hash)

Least Connections

- LB tracks active connection count per server. New request → server with fewest.
- Problem: a server with 3 idle connections receives the same treatment as one with 3 active heavy queries
- Works well when requests are similar in duration (e.g., short API calls)

Weighted Least Connections

- $\text{Ratio} = \text{active_connections} / \text{server_weight}$
- S1(8 conns, $w=4$) $\text{ratio}=2.0$ vs S2(3 conns, $w=2$) $\text{ratio}=1.5$ → route to S2
- Best of both worlds: real-time load AND server capacity considered
- Most production environments use this as their default dynamic algorithm

Least Response Time

- $\text{Score} = \text{active_connections} \times \text{TTFB}$. Lower score = route there.
- TTFB automatically captures both how busy the server is AND how fast it processes requests
- If two servers tie on score, fallback to Round Robin between them
- Requires constant monitoring — adds ~1ms overhead per health check cycle
- Best for heterogeneous workloads where response time varies significantly

7. Complete Algorithm Comparison

All Algorithms — Quick Reference

Algorithm	Type	Metric	Pros	Cons	Best when
Round Robin	Static	Cyclic sequential	Simple, equal dist.	Ignores capacity complexity	identical servers
Weighted Round Robin	Static	Cyclic with weights	Handles capacity diff.	Ignores request processing time	mixed capacity
IP Hash	Static	hash(client IP)	Session affinity	Proxy = all traffic one server	session persist
Least Connections	Dynamic	Min active connections	Real-time adaptation	Ignores traffic volume/conn	high conn variety
Weighted Least Conn	Dynamic	conns / weight ratio	Load + capacity aware	Weights set manually	mixed + capacity
Least Response Time	Dynamic	conns × TTFB score	Most accurate routing	Monitoring overhead	perf-critical

6 algorithms across: type, metric, pros, cons, best when

8. Quick Revision & Interview Questions

Quick Revision

- > Load balancer = distributes requests across servers. Prevents single server bottleneck.
- > L4 LB: routes by IP+port at Transport Layer. Fast, simple, no content inspection.
- > L7 LB: routes by headers/URL/cookies at Application Layer. Smart, caching, session-aware.
- > Static algorithms: do not monitor server state. Fixed rules. Simpler but less adaptive.
- > Dynamic algorithms: monitor real-time metrics. More accurate but more complex.
- > Round Robin: cyclic. Equal distribution. No capacity awareness. Best for identical servers.
- > Weighted Round Robin: capacity weights. S1(w=4) gets 4x more than S3(w=1).
- > IP Hash: hash(IP) → same server. Session affinity. Breaks behind shared proxy/NAT.
- > Least Connections: route to server with fewest active connections. Real-time.
- > Weighted Least Conn: route to min(conns/weight). Best for mixed-capacity + real-time.
- > Least Response Time: score = conns × TTFB. Route to lowest score. Most accurate.
- > TTFB = Time to First Byte. Measures server responsiveness. Used in Least Response Time.
- > Tie in Least Response Time → fall back to Round Robin between tied servers.
- > Production default: Weighted Least Connections (real-time + capacity aware).
- > Session persistence via IP Hash is risky — prefer sticky cookies for stateful apps.

Interview Questions

1. What is a load balancer and why is it needed?
2. What is the difference between an L4 and L7 load balancer?
3. Explain Round Robin. When does it break down?
4. What problem does Weighted Round Robin solve over plain Round Robin?
5. Why can IP Hash cause uneven load? How would you fix it?
6. Explain Least Connections. What is its limitation?
7. How does Weighted Least Connections work? Give a worked example.
8. What is TTFB? How is it used in Least Response Time?
9. When would you use a static algorithm vs a dynamic one?
10. If you had servers with different CPU/RAM specs, which algorithm would you pick?

- 11. How does a load balancer support high availability? What happens when one server fails?
- 12. Design a load balancing strategy for a payment API serving 1M requests/day.

Key Terms

Load Balancer	Distributes incoming requests across multiple servers to prevent overload
L4 LB	Network LB — routes by IP + TCP/UDP port. Fast, no content inspection.
L7 LB	Application LB — routes by headers, URL, cookies. Smart, supports caching.
Round Robin	Cyclic request distribution: S1, S2, S3, S1... No capacity awareness.
Weighted RR	Round Robin with capacity weights. Higher weight = more requests.
IP Hash	hash(client IP) → always same server. Session affinity. Proxy-unsafe.
Least Connections	Route to server with fewest active connections. Dynamic.
Weighted Least Conn	Route to min(conns/weight). Dynamic + capacity aware.
Least Response Time	Score = conns × TTFB. Route to lowest score. Most accurate.
TTFB	Time to First Byte — interval from request sent to first byte received.
Static Algorithm	Uses fixed rules, no real-time server monitoring.
Dynamic Algorithm	Monitors live server state and adapts routing in real time.
Session Affinity	Same client always routed to same server (sticky sessions).
Health Check	LB periodically checks if servers are alive and responsive.
