## Part 1 · Distributed Transaction Handling

ACID · 2PC · 3PC · Saga Pattern · WAL Logs

### 1. What is a Transaction? — ACID Properties

A **transaction** is a group of operations that execute atomically — all succeed, or all fail. The classic example: transferring Rs.1000 from Account A to Account B requires two operations (debit A, credit B). If debit succeeds but credit fails, money disappears. Transactions prevent this.

| Property    | What it means                              | Bank Transfer Example                  |
|-------------|--------------------------------------------|----------------------------------------|
| Atomicity   | All ops succeed or all are rolled back     | Debit A AND credit B — never just one  |
| Consistency | DB moves from one valid state to another   | Total money before = total money after |
| Isolation   | Concurrent txns do not see partial changes | Two transfers do not interfere         |
| Durability  | Committed changes survive system crashes   | Power cut after commit → data persists |

### 2. Why Distributed Transactions Fail

In a single-DB monolith, ACID is enforced natively. In microservices, each service owns its own DB. One business operation (e.g. place an order) spans **Payment Service**, **Order Service**, **Inventory Service** — each with an independent transaction manager. There is no shared coordinator.

#### Why Distributed Transactions? — The Problem

Single DB: ACID guaranteed natively · Distributed DBs: each commits independently → partial failures → inconsistency

### 3 & 4. Two-Phase Commit (2PC) — Deep Dive

2PC uses a **Transaction Coordinator** to achieve global atomicity across multiple services. All participants must agree before any commits. A single NO vote aborts the entire transaction.

#### Two-Phase Commit (2PC) — How it Works

##### Phase 1 — Prepare (Voting)

Coordinator sends PREPARE to all participants.  
Each participant: locks resources, writes to WAL log.  
Responds YES (ready) or NO (cannot commit).  
All YES → Phase 2 Commit. Any NO → ABORT all.

##### Phase 2 — Commit / Abort (Decision)

All YES → Coordinator sends COMMIT to all.  
Participants: apply changes, release locks.  
Any NO → Coordinator sends ABORT to all.  
Participants: roll back, release locks.

##### Failure Scenarios:

Coordinator crash after PREPARE → participants locked and WAITING — blocked indefinitely (BLOCKING PROBLEM).  
Participant crash → coordinator aborts after timeout.  
WAL Log: both sides write state before acting. On restart, replay log to re-send correct decision.

2PC: Coordinator → PREPARE → all vote → COMMIT or ABORT · Phase explanations below the flow

| Failure Scenario                  | What Happens                                               | Recovery                                                |
|-----------------------------------|------------------------------------------------------------|---------------------------------------------------------|
| Coordinator crashes after PREPARE | Participants locked, waiting indefinitely — BLOCKING       | Coordinator restarts, replays WAL log, resends decision |
| Participant crashes               | Does not respond to PREPARE → timeout → coordinator ABORTs | Participant reads WAL on restart, coordinator retries   |
| Commit message lost               | Participant never commits, stays locked                    | Coordinator retries COMMIT until ACK received           |

WAL (Write-Ahead Log): Both coordinator and participants write state to durable log BEFORE acting.

States logged: PREPARE SENT → PREPARED → COMMIT DECISION → COMMITTED → ABORTED

On crash restart: replay WAL log to determine in-progress transactions and re-send correct message.

XA Standard: PostgreSQL, MySQL, Oracle support 2PC natively via XA protocol.

## 5. Three-Phase Commit (3PC)

3PC adds a **Pre-Commit** phase. After all participants vote YES, the coordinator sends Pre-Commit before asking them to act. Participants now **know the decision**. If coordinator crashes, they can act autonomously after a timeout — no more indefinite blocking.

### Three-Phase Commit (3PC) — Non-Blocking Improvement

#### Why 3PC is Non-Blocking — The Key Insight

**2PC problem:** After Phase 1, participants are locked and WAITING. If coordinator crashes, nobody knows the decision → BLOCKED FOREVER.

**3PC fix:** Pre-commit phase tells participants the decision BEFORE asking them to act. If coordinator crashes after pre-commit, participants already know the decision and can proceed independently after a timeout.

**In practice:** 3PC is rarely used in production — high message overhead + complexity. Real systems use Saga Pattern or Consensus (Raft/Paxos) instead.

3PC: Prepare → Pre-Commit (decision known) → Commit · Non-blocking on coordinator failure · Rarely used in practice

## 6 & 7. Saga Pattern — Asynchronous Distributed Transactions

The Saga Pattern replaces one global transaction with a sequence of local transactions. Each service commits locally and publishes an event. On failure, **compensating transactions** are triggered in reverse. No global locks. Suitable for microservice workflows.

### Saga Pattern — Asynchronous Distributed Transactions

#### Happy Path (all succeed) — Amazon Order Example

#### Failure Path — Inventory fails, compensations triggered

Compensating transactions triggered in REVERSE order:

#### Saga Pattern vs 2PC — Key Differences

|                  |                               |                                      |
|------------------|-------------------------------|--------------------------------------|
| Nature           | Synchronous — blocking        | Asynchronous — non-blocking          |
| Locking          | Locks resources until commit  | No locks — immediate local commit    |
| Failure handling | Global abort — all roll back  | Compensating transactions in reverse |
| Use case         | Short, atomic DB transactions | Long-running microservice workflows  |
| Consistency      | Strong (ACID)                 | Eventual consistency                 |
| Real-world use   | Bank transfers, payments      | E-commerce orders, booking systems   |

Saga: each service commits locally → emits event → next service starts · Failure triggers compensations in reverse

Compensating transaction  $\neq$  DB rollback. It is a NEW forward operation that semantically undoes the committed step.

Saga Choreography: services react to events directly. No central coordinator.

Saga Orchestration: central orchestrator sends commands and tracks overall state (used by AWS Step Functions).

Saga gives EVENTUAL consistency — the system converges to a correct state over time.

## 8. Protocol Comparison

### Protocol Comparison Real-World Usage

| Two-Phase Commit (2PC)<br>Synchronous · Blocking | Three-Phase Commit (3PC)<br>Synchronous · Non-blocking | Saga Pattern<br>Asynchronous · Non-blocking |
|--------------------------------------------------|--------------------------------------------------------|---------------------------------------------|
| All participants must vote YES                   | Same as 2PC + Pre-Commit phase                         | Each service commits locally                |
| Coordinator decides commit/abort                 | Participants know decision before acting               | Event-driven via message queue              |
| Participants wait for decision                   | Can proceed if coordinator fails                       | On failure: compensate in reverse           |
| Blocking if coordinator crashes                  | Timeout-based self-resolution                          | No global lock manager needed               |
| WAL logs for recovery                            | Participants can query each other                      | Best for microservices                      |
| + Strong ACID guarantees                         | + Non-blocking — no indefinite wait                    | + No long locks — high scalability          |
| + Widely supported (XA standard)                 | + Participants act autonomously                        | + Works across microservices                |
| - Blocking under failure                         | - High message complexity                              | - Only eventual consistency                 |
| - Not suited for long txns                       | - Rarely used in production                            | - Compensations can be complex              |
| Used by:                                         | Used by:                                               | Used by:                                    |
| • Bank transfers                                 | • Rarely used — replaced by Consensus algorithms       | • Amazon orders                             |
| • RDBMS clusters                                 |                                                        | • Uber rides                                |
| • Payment processing                             |                                                        | • Netflix content delivery                  |

2PC vs 3PC vs Saga — locking, failure handling, consistency, real-world usage

### Quick Revision — Part 1

- > ACID: Atomicity, Consistency, Isolation, Durability — enforced natively on single DB.
- > Distributed txn problem: each service has its own DB and tx manager — partial commits possible.
- > 2PC Phase 1 (Prepare): Coordinator → PREPARE → participants lock, vote YES/NO.
- > 2PC Phase 2 (Commit): All YES → COMMIT all. Any NO → ABORT all.
- > 2PC problem: Coordinator crash after PREPARE → participants BLOCKED indefinitely.
- > WAL log: records state before acting. Used for recovery on restart.
- > 3PC: adds Pre-Commit phase — participants know decision, can act alone on timeout.
- > 3PC rarely used: high complexity, message overhead, network assumption issues.
- > Saga: local commits + events. Failure → compensating transactions in reverse.
- > Compensation = new forward op. Refund ≠ rollback. Cancel order ≠ undo.

Part 2 · BookMyShow — Case Study

Applying distributed transaction concepts to a real-world ticket booking system

9 & 10. The Two Core Problems & Seat Reservation Flow

**BookMyShow** faces two simultaneous distributed systems challenges: **Concurrency** (two users clicking Seat A1 at the exact same moment) and **Distributed Transactions** (booking spans Seat, Payment, Food, and Notification services — each owning its own DB).

| Problem         | Scenario                                          | Challenge                                      | Solution                                      |
|-----------------|---------------------------------------------------|------------------------------------------------|-----------------------------------------------|
| Concurrency     | Two users click Seat A1 simultaneously            | Both see it as available → double booking      | 2PL — row-level locks on seat table           |
| Distributed Txn | Seat reserved, payment charged, food fails        | Partial state — money taken, food not reserved | Saga Pattern with per-step compensation       |
| Stale Reads     | User sees seat available while another is booking | Race condition window                          | Reservation TTL + RESERVED state acts as lock |

Seat states: AVAILABLE→RESERVED(5-min TTL)→CONFIRMED · Payment failure auto-releases → AVAILABLE · No global locks

## 11 & 12. Two-Phase Locking vs Two-Phase Commit — and Why 2PC Fails at Scale

2PL (Two-Phase Locking): Concurrency control **INSIDE** one database. Acquires row locks during reservation, releases on commit/rollback.

2PC (Two-Phase Commit): Atomic commit **ACROSS** multiple databases/services. Coordinator asks all to prepare, then commit or abort.

BookMyShow uses 2PL for the seat table (single SQL DB). It does **NOT** use 2PC across services — too slow at scale.

In theory, 2PC could coordinate all BookMyShow services globally. In practice at Avengers premiere scale (10M users), it catastrophically fails:

| 2PC Problem         | Impact on BookMyShow                                             | Why Catastrophic at Scale                         |
|---------------------|------------------------------------------------------------------|---------------------------------------------------|
| Blocking protocol   | Coordinator crash → ALL services wait. Millions of users frozen. | 10M users queued → mass timeouts → revenue loss   |
| Long lock hold      | Seats locked during payment (10-30s). Others blocked.            | 100K seats locked × 30s = massive contention      |
| Coordinator SPOF    | One coordinator handles all transactions.                        | Single point of failure for entire booking system |
| Network sensitivity | All Prepare/Commit messages must succeed.                        | 0.1% packet loss → abort rate unacceptable        |

### 13. Saga Pattern Applied to BookMyShow Booking Flow

BookMyShow uses a **Saga Orchestrator** (a Booking Service) that sends commands to each downstream service and tracks the overall booking state. Each service commits locally and reports success/failure to the orchestrator.

#### BookMyShow — Saga Pattern for Booking Workflow

**Key Insight:** Popcorn failure does NOT cancel confirmed seats — business logic decides compensation per step.

**Saga compensation:** Refund popcorn only · Seats remain CONFIRMED · Notify user about food unavailability

#### Compensation Strategy per Service

| Service     | Forward Transaction | Compensating Transaction | Consistency Level                |
|-------------|---------------------|--------------------------|----------------------------------|
| Seat Svc    | Reserve A1-A4       | Release seats            | Critical — strong consistency    |
| Payment Svc | Charge Rs.500       | Refund Rs.500            | Critical — immediate compensate  |
| Food Svc    | Reserve popcorn     | Refund food only         | Non-critical — Saga compensation |
| Notif Svc   | Send e-ticket       | Send cancellation        | Async — retry on failure         |

BMS Saga: Seat→Payment→Food→Notification · Food failure only compensates food — seats stay CONFIRMED · Business-driven

#### Key Insight — Business-Driven Compensation

Saga does NOT mean "rollback everything". Each step defines its **own compensation logic** based on business criticality. A popcorn order failing does NOT cancel confirmed seats.

| Service     | Forward Transaction      | Compensating Transaction  | Compensation Logic                            |
|-------------|--------------------------|---------------------------|-----------------------------------------------|
| Seat Svc    | Reserve A1-A4 → RESERVED | Release seats → AVAILABLE | Only if payment fails BEFORE confirmation     |
| Payment Svc | Charge Rs.500            | Refund Rs.500 to card     | Always on booking cancellation                |
| Food Svc    | Reserve popcorn          | Refund food amount only   | Seats remain CONFIRMED — food is non-critical |
| Notif Svc   | Send e-ticket            | Send cancellation email   | Async — retry on failure, eventual delivery   |

## 14 & 15. Strong vs Eventual Consistency — Final Architecture

### BookMyShow — Strong vs Eventual Consistency by Component

Critical path (seats+payment): SQL ACID + 2PL + idempotency · Non-critical (food+notif): Saga + async queues

| Component            | Consistency Level | Mechanism                               | Reason                                        |
|----------------------|-------------------|-----------------------------------------|-----------------------------------------------|
| Seat reservation     | Strong            | SQL ACID + 2PL row locks + TTL          | Double booking = catastrophic user experience |
| Payment processing   | Strong            | Local ACID tx + idempotency key         | Money errors = legal and financial liability  |
| Booking confirmation | Strong            | Atomic DB update (seat+booking record)  | Must be all-or-nothing — no partial booking   |
| Food inventory       | Eventual          | Saga + compensation (refund food)       | Food unavailable → refund, seats still valid  |
| Notifications        | Eventual          | Async queue + exponential backoff retry | Delayed email is acceptable, not critical     |
| Loyalty points       | Eventual          | Async event stream                      | Minor reward, small delay is fine             |
| Analytics            | Eventual          | Kafka event streaming                   | Reporting lag of seconds/minutes is OK        |

## 16. Quick Revision & Interview Questions

### Quick Revision — Part 2 (BookMyShow)

- > BMS has 2 problems: Concurrency (same seat, same time) + Distributed Txn (multi-service booking).
- > Seat states: AVAILABLE → RESERVED (5-min TTL) → CONFIRMED (payment ok) or EXPIRED (timeout/failure).
- > 2PL = DB-level row locking. 2PC = cross-service atomic commit. Different problems, different tools.
- > BMS uses 2PL for seat table concurrency. Does NOT use 2PC — too slow at 10M concurrent users.
- > Reservation model: seat rows locked locally. TTL auto-releases if user abandons. No global locks.
- > BMS uses Saga Orchestration: Booking Orchestrator tracks overall state, sends commands to each service.
- > Food failure → compensate food only (refund). Seats REMAIN CONFIRMED. Business-driven.
- > Compensation = new forward op. Refund ≠ DB rollback. Cancel ≠ undo.
- > Critical path (seats + payment): STRONG consistency — SQL ACID + locks + idempotency keys.
- > Non-critical path (food + notif): EVENTUAL consistency — Saga + async queues.
- > Interview answer template: "For seats I use 2PL + reservation TTL. For cross-service I use Saga. No global 2PC."

### Interview Questions — Combined

- 1. What is a distributed transaction? Why can't you use normal DB transactions across microservices?
- 2. Explain Two-Phase Commit end to end with a sequence diagram.
- 3. What happens if the 2PC coordinator crashes after PREPARE? How does WAL help?
- 4. How does 3PC solve 2PC's blocking problem? Why is it rarely used?
- 5. Explain the Saga Pattern. What is a compensating transaction?
- 6. Two users book Seat A1 simultaneously — how does BookMyShow prevent double booking?
- 7. What is the seat state machine in BookMyShow? Explain the TTL mechanism.
- 8. What is the difference between 2PL and 2PC? When does BMS use each?
- 9. Why doesn't BookMyShow use 2PC across all services at Avengers premiere scale?
- 10. Popcorn order fails after seats are confirmed — walk through the Saga compensation.
- 11. Which BookMyShow services need strong consistency? Which can use eventual? Why?
- 12. Design the seat reservation system — DB schema, locking strategy, TTL, and failure handling.
- 13. What is the difference between Choreography and Orchestration Saga? Which does BMS use?

### Key Terms — Full Glossary

|                     |                                                                                       |
|---------------------|---------------------------------------------------------------------------------------|
| <b>ACID</b>         | Atomicity, Consistency, Isolation, Durability — DB transaction guarantees             |
| <b>2PC</b>          | Two-Phase Commit — Prepare (vote) + Commit/Abort. Coordinator orchestrates. Blocking. |
| <b>3PC</b>          | Three-Phase Commit — adds Pre-Commit. Non-blocking but rarely used.                   |
| <b>Saga Pattern</b> | Sequence of local commits with compensating transactions on failure. Async.           |
| <b>2PL</b>          | Two-Phase Locking — DB concurrency control. Acquire locks then release. Not 2PC.      |
| <b>WAL Log</b>      | Write-Ahead Log — durable state record for crash recovery in 2PC/3PC                  |

|                             |                                                                              |
|-----------------------------|------------------------------------------------------------------------------|
| <b>XA Standard</b>          | Industry standard for 2PC across databases (PostgreSQL, MySQL support it)    |
| <b>Compensation</b>         | New forward operation that semantically undoes a committed local transaction |
| <b>Choreography</b>         | Saga where services react to events independently — no central coordinator   |
| <b>Orchestration</b>        | Saga where a central orchestrator sends commands and tracks overall state    |
| <b>RESERVED state</b>       | BMS seat locked by a user for 5 minutes — others see it as unavailable       |
| <b>Reservation TTL</b>      | 5-minute expiry on RESERVED seats — auto-releases on payment failure         |
| <b>Strong Consistency</b>   | Immediate correctness — seats, payment. Uses 2PL + ACID transactions.        |
| <b>Eventual Consistency</b> | Converges to correct state over time — notifications, food, analytics.       |
| <b>Idempotency Key</b>      | UUID preventing duplicate payment charges on retry                           |
